2.5 From 115 GeV to 1 TeV
An interesting comparison can be made between the experimental approach to the Higgs boson searches at LEP with those under preparation for the LHC. After early experimental measurements closed the door to the possibility of a Standard Model Higgs boson with a mass in the range 0 – 60 GeV, a new era of direct searches for on-shell diboson (ZH) production began in 1996 when LEP increased the center-of-mass energy above \( \sim 160 \) GeV and continued through 2000 to the ultimate LEP energy reach of \( \sqrt{s} = 209 \) GeV. During this time, the event signatures were categorized according to the decay modes of the predicted Higgs boson and the well-studied decay widths of the Z boson, as shown in Figure 1.

![Figure 1: Topologies involved in the search for the standard-model Higgs boson at LEP2, missing energy, lepton pairs, \( \tau^+\tau^- \), four-jets.](image)

Coverage was essentially complete (\( \sim 90\% \)) achieving a maximum detection efficiency with varying degrees of sensitivity to the observation of a Higgs boson above Standard Model background processes with similar experimental signatures. The closest “Higgs-like” backgrounds came from ZZ production with at least one Z boson decaying to \( b\bar{b} \), noting the finite and non-Gaussian detector resolution on the measurement of the dijet \( b\bar{b} \)-mass. An example four-jet event is shown in Figure 2.

Many analysis techniques were used to quantify the agreement of the overall contributions of Standard Model processes to the Higgs search background predictions, and in all cases the level of agreement was exceptional with comparably small theoretical and experimental uncertainties. Therefore, background systematic uncertainties have little contribution to the overall search sensitivity. An important aspect of the LEP searches was the use of full-event discrimination that was sensitive to event counting as well as properties such as reconstructed mass. The final LEP measure of the Higgs search data quantified both mass and rate information, as shown in Figure 4, where the presence of a Higgs boson signal formed a minimum in the likelihood ratio.

References:
LEP was thoroughly limited by statistics at the highest achievable energies as the ZH cross section turns on rapidly above threshold, as shown in Figure 3. With four LEP experiments, sensitivity to a 60 fb cross section at the kinematic limit of $m_H = \sqrt{s} - m_Z$ was achieved with $\sim 200$ pb$^{-1}$ delivered per experiment. In the missing energy channel of the Higgs search, some contribution to the sensitivity came from WW fusion, a process whereby both the incoming positron and electron covert to neutrinos radiating W bosons which fuse to form the Higgs boson, as shown in Figure 5. This exceptional process becomes a larger fraction of the total Higgs
production rate with increasing beam energy. An example missing energy event is shown in Figure 6.

![Diagram of Higgs-strahlung and weak boson fusion processes of Higgs boson production at LEP2.](image)

Figure 5: Diagrams of the Higgs-strahlung and weak boson fusion processes of Higgs boson production at LEP2.

![L3 missing energy event.](image)

Figure 6: L3 missing energy event.

At the LHC, the approach of creating a full matrix of predicted Higgs production and associated decay processes is still a necessary starting point for the construction of the analyses, while judicious choices of processes are needed to accommodate the triggering capabilities of the experiment. There is less reliance on singular search channels in particular for channels involving jets and transverse missing energy. Search channels with multijet QCD backgrounds tend to be more inclusive in order to simultaneously fit the dominant Standard Model background fractions. Some backgrounds are necessarily estimated using data-based samples as opposed to Monte Carlo simulation. The possibility of concurrent signals such as from multiple Higgs bosons and the presence of SUSY particle production also warrant wider event sample scrutiny, not to mention the large experimental challenges of commissioning the detector in all necessary aspects of the measurement.

The justification for the many experimental “warning flags” for LHC analyses is discussed in the following
sections. The many possible manifestations of the Higgs boson discovery and crucial first measurements are also discussed.

1.1 Probing Deep within the Proton

The first step towards understanding phenomenology at the Large Hadron Collider is to quantify the influence of the proton parton distribution functions (PDF).

PDFs describe the fraction of the proton momentum carried by the quarks, anti-quarks (by flavor) and gluons at a scale $Q^2$ in momentum transfer corresponding to the hard collision.

1.1.1 Parton Model for Proton-Proton Collisions

The initial kinematics are described by the incoming proton momentum, $P = 7$ TeV, and partons $i$ with longitudinal momentum fractions, $x_i$ ($0 \leq x_i \leq 1$). The 4-momenta and center-of-mass energy are approximated by:

$$p_{1,2} = x_{1,2}P, \quad s = x_1 x_2 s = \tau s$$  \hspace{1cm} (1)$$

and the rapidity $y$ is given by

$$y = \frac{1}{2} \ln \left( \frac{E + p_z}{E - p_z} \right) = \frac{1}{2} \ln \frac{x_1}{x_2}$$  \hspace{1cm} (2)$$

with $x_{1,2} = \sqrt{\tau e^\pm y}$.

Exercise: Show rapidity differences $\Delta y$ are invariant under longitudinal boosts.

Answer:

$$E \rightarrow E' = \gamma E + \gamma \beta p_z \text{ and } p_z' = \gamma \beta E + \gamma p_z$$

Therefore,

$$y' = \frac{1}{2} \ln \left( \frac{E' + p_z'}{E' - p_z'} \right) = y + \frac{1}{2} \ln \left( \frac{1 + \beta}{1 - \beta} \right)$$

Therefore, $\Delta R = \sqrt{\Delta \phi^2 + \Delta y^2}$ is an invariant angular measure. Note, in the limit of massless particles

$$E \pm p_z = p(1 \pm p_z/p) = p(1 \pm \cos \theta)$$

$$y \rightarrow \eta = \frac{1}{2} \ln \left( \frac{1 + \cos \theta}{1 - \cos \theta} \right) = -\ln \tan \frac{\theta}{2}$$

where $\eta$ is the pseudo-rapidity.

For computing transverse components of momenta, note the relationship $\sin \theta = 1/ \cosh \eta$.

PDF distributions are fits to experimental data and theoretical extrapolations. An online source for these databases is:

http://durpdg.dur.ac.uk/hepdata/pdf3.html
Higgs, jet (M(E - 5b = 150 GeV) (E_s/20) T = 500 GeV) -6 5

The expected ratio of positively to negatively charged electrons and muons as a function of rapidity from selected
-the top quark to be discovered in 1995.

Most of the interesting reactions at the LHC are hard scattering processes of the partons inside the protons. There-
the Tevatron had to be a fixed target experiments and at the electron-proton collider HERA. As the overlap of both regions are small theo-

Figure 1: Left: Cross sections of various SM processes in (anti)proton-proton collision in the Tevatron and LHC

Figure 7: The PDF distributions for Q^2 = 4m_t^2, showing that the Tevatron had to be a p\bar{p} collider for the top quark to be discovered in 1995.

Figure 8: Regions of Q^2 and x to be probed at the LHC.
The relationships (1) and (2) can be tested against the rapidity distributions of \( W \) and \( Z \) boson production at the Tevatron. Using max. \( x = 1 \), the \( Z \) boson can be produced for rapidities satisfying

\[
1 \geq \frac{m_Z}{1.96 \ \text{TeV}} e^y
\]  

which gives \( y < 3 \), as shown in Figure 10.

![Figure 9: Charge asymmetry of \( W \) bosons at the Tevatron.](image)

![Figure 10: Rapidity of \( Z \) bosons produced at the Tevatron.](image)

The \( W \) boson rapidity has a charge asymmetry due to the larger \( x \)-values of the \( u \)-(anti)quarks in the (anti)proton compared to \( d \)-(anti)quarks, as shown in Figure 9. At the LHC, the \( Z \) bosons will be peaked backward and forward, corresponding to which proton supplied the (low \( x \)) antiquark for the \( q\bar{q} \) annihilation.
1.2 More Orders of Magnitude than EWK to GUT

The LHC will begin taking data in 2007 with an initial target luminosity of $\mathcal{L} = 2 \times 10^{34} \text{cm}^{-2}\text{s}^{-1}$. Approximately 400 $W$, 100 $Z$ bosons and 2 $tt\bar{t}$ pairs will be produced per second.

Experiments handle the large spectrum of rates with trigger systems. For instance, low $p_T$ dijet production is the dominant process at hadron colliders. While at the same time, high $p_T$ dijets probe the smallest length scales. Measuring the cross section over a range of 10 orders of magnitude is important as it yields a running value of $\alpha_s(Q^2)$. 
This type of spectrum is recorded with separate triggers, each of which having a different jet $p_T$ threshold and prescales (only every $N$ events recorded).

Figure 11: Dijet trigger prescales.

The actual cross section measurement is a piece-wise assembly of several separate triggers. Only fully efficient regions of the trigger are kept and the lowest trigger is dropped from the analysis. The turn-on curve for a trigger is a function of the jet resolution and detector uniformity. In these examples, the dijet mass spectrum is covered
down to 500 GeV with prescales, and only 2 TeV dijet resonances are in unprescaled trigger regions.

All datasets are heavily affected by the trigger or triggers used to select them. The trigger path defines a narrow sieve through which a tremendous downpour of multijet QCD events could pass, most of which as instrumental backgrounds to be defined loosely as anomalous measurements due to finite detector resolution or coverage. Tables 15 and 16 show initial estimates for the hardware and software online trigger thresholds, respectively, for the CMS experiment.

**Table 15-2**: High-Level Trigger requirements at low luminosity. The thresholds correspond to the values in $E_T$ or $p_T$ with 95% efficiency (90% efficiency for muons). There is no actual threshold in the HLT selection for 1-jets, so the threshold shown is that of the corresponding Level-1 Trigger requirement.

**Figure 15**: Level-1 Trigger Table. **Figure 16**: High-Level Trigger Table.

The total acceptance rate to tape for an LHC experiment is $\sim 150$ Hz (event sizes are $\sim 1$ MByte). The rate of leptonic W decays alone exceeds the bandwidth. The rate of Z boson dileptons is $\sim 10$ Hz. If we had purely electroweak processes, then the triggers could manage this task easily. However, the rate of dijet $b\bar{b}$ production where at least one B-hadron semileptonically decays is over $10^5$ Hz exceeding the hardware trigger limitations. Dijet $b\bar{b}$ production is a lepton factory. Therefore, the only way to control the single and dilepton triggers is to require the leptons to be isolated from jets, as most “soft-lepton”-tagged $b$-jets will contain the lepton within $\Delta R < 0.5$ separation. Jet directions are difficult to reconstruct at hardware-level, so most online isolation criteria are based on “hollow cones” centered on the lepton candidate, either in the calorimeter at level-1 or including the tracks at the higher-level software trigger. Lepton isolation criteria will have to fight against inefficiencies from underlying event, pile-up and magnetic field spreading of low $p_T$ pions.

The trigger rates at the LHC startup will be a major test of the preparatory work in progress at the CMS and
ATLAS experiments. If the initial trigger rates exceed expectation, methods to tighten isolation criteria to control the rate will be invaluable. Directly raising the thresholds on jets and leptons will cut into vital Higgs boson signal efficiencies.

1.3 Multijet QCD Backgrounds

With such a high rate of multijet events, a single electron trigger, for example, will select some number of jets as electrons. This can be due to fragmentation or detector response fluctuations or other, that are difficult to model with finite Monte Carlo simulation statistics. Data-driven estimates are required for singly-important selection criteria, for example, a high $p_T$ isolated electron.

**Method:** use electrons from $Z \rightarrow ee$ decay

Figure 17: To verify the MC prediction for the signal efficiency $\epsilon_{\text{sig}}$, the data-to-MC efficiencies are compared using a “tag and probe” method on $Z \rightarrow ee$ data.

One technique to determine the normalization of the multijet background is to apply a “matrix method” from simultaneous equations sensitive to the differences in behavior when tightening electron identification. One defines two samples, tight and loose. The efficiency for a true isolated electron to pass the tight cuts is given by $\epsilon_{\text{sig}}$ and for multijet background to pass a fake electron, the efficiency is $\epsilon_{\text{QCD}}$. The set of linear equations are therefore:

$$N_{\text{loose}} = N_{\text{sig}} + N_{\text{QCD}}$$

$$N_{\text{tight}} = \epsilon_{\text{sig}} N_{\text{sig}} + \epsilon_{\text{QCD}} N_{\text{QCD}}$$

(4)

The efficiency $\epsilon_{\text{sig}}$ may be taken from Monte Carlo simulation after data-to-MC scale factors are applied, see “tag and probe” in Figure 17. Note, the normalization depends on the jet multiplicity in the event.

The efficiency for fake electrons to pass the tight cuts is measured directly from data. For example, for signals
with transverse missing energy, the low $E_T$ region will be dominated by background, and $\epsilon_{QCD}$ is the ratio of tight to loose events in this background-enhanced sample, as shown in Figure 18.

![Figure 18: Ratio of tight to loose as a function of $E_T$ where extrapolation to the low $E_T$ region gives a stable value for $\epsilon_{QCD}$.

The value of $\epsilon_{QCD}$ can depend strongly on shape and threshold parameters in the trigger selection. The background shape is taken directly from the background-enhanced sample and added to the prediction with the matrix method normalization, as shown in Figure 19.

![Figure 19: Example of the leptonic W transverse mass from the Tevatron in events with at least one $b$-tagged jet. Background shape from QCD multijets is in grey with a normalization determined from the “matrix method”.

### Figure 18: Ratio of tight to loose as a function of $E_T$. For events in the second inclusive jet multiplicity bin, obtained separately for events that were selected with trigger versions 8-11, 12, and 13. A fit to these distributions gives a stable $\epsilon_{QCD}$ value for different exclusive jet multiplicities in the $e+\nu$ analysis, with their respective statistical errors. We observe no dependence of $\epsilon_{QCD}$ as a function of the second inclusive jet multiplicity (i.e., events with 2 or more jets) to calculate the value of $\epsilon_{QCD}$ used in the analysis.
Folding the Higgs production cross sections and branching fractions (Figs. 20 and 21) against the trigger and selection efficiencies, a preliminary list of relevant search channels for a low mass Higgs search can be formed. This is given in Table 1. Of the channels in the left-most column, only the diboson decays of the Higgs are sufficiently clean to be detected inclusively within corresponding specific trigger paths. The columns to the right are a set of exclusive decay channels where identification of associated production particles give at least an order of magnitude improvement in signal to background separation, relative to the inclusive searches. The exclusive channels have unique sensitivities to $3^{rd}$ generation Higgs couplings, tree-level electroweak couplings and more precise mass and partial decay width measurements.

In the 20 GeV mass range between the WW and ZZ-thresholds, the inclusive WW channel is the dominant decay mode with substantial statistics to form a transverse mass measurement of the Higgs. Above the ZZ-threshold, the four-lepton decay is the golden channel for Higgs discovery with low backgrounds and high resolution mass reconstruction in a mixture of pairs of dielectron and dimuon decays.

At the highest masses, the dropping production cross sections are compensated by the addition of hadronic W and Z decay modes. The high $p_T$ boson signature has lower backgrounds and the dijets begin to merge, providing a clear massive monojet signature. Similarly, the neutrino decays of high $p_T$ Z bosons provide a substantial transverse missing energy. These highly boosted diboson decays provide Higgs boson search coverage up through 1 TeV where the width of the Higgs becomes comparable to its mass and the electroweak scattering of massive weak bosons will begin to form resonances in a semi-strong coupling regime.

Table 1: The most important SM Higgs channels for $m_H$ below the WW-threshold.
2.1 High Mass Resolution Search Channels

The sub-threshold decay of the Higgs boson to $ZZ^*$ is kinematically similar to the semileptonic $b$-quark decay in that dominantly one $Z$ boson is nearly on-shell and the second $Z$ boson has a mass corresponding to the remaining $Q^2$ of the decay. Therefore, a 130 GeV Higgs boson will decay into a $\sim 90$ GeV and a less than 40 GeV pair of $Z$ bosons. The soft $Z$ boson decay into leptons is problematic in terms of lepton backgrounds and reconstruction efficiency. Ultimately, low $p_T$ lepton detection and diminishing $ZZ^*$ branching fraction limit this channel to above 130 GeV.

Background to $H \rightarrow 4\ell$ comes from $t\bar{t}$ dilepton decays with both $b$-jets producing leptons from semi-leptonic...
decays. Similarly, the process $Zb\bar{b}$ is also a background with a $Z$ decaying to leptons and each $b$-jet producing a lepton (for background studies replace “$b$” everywhere with lepton). Note, leptons from B-hadron semileptonic decay can be partially removed using impact parameter techniques ($4\ell$ vertex probability) as well as lepton isolation.

The above-threshold $H \rightarrow ZZ$ decay has background from on-shell $ZZ$ production, as shown in Figure 23. The

![Figure 23: The $H \rightarrow ZZ^* \rightarrow 2e2\mu$ mass distributions before (top) and after (bottom) final selections for $m_H = 130$ GeV (left) and $m_H = 200$ GeV (right).](image)

number of selected signal and background varies strongly with mass as shown in Figure 24 with a corresponding signal significance shown in Figure 25. With a mass resolution of $1.0 \sim 1.2\%$, the direct measurement of the width $\Gamma_H$ becomes possible above $\sim 200$ GeV as shown in Figure 26.
2.1 High Mass Resolution Search Channels

Figure 24: Cross section after acceptance $H \rightarrow 2e2\mu$.

Figure 25: Signal significance for $H \rightarrow 2e2\mu$.

Figure 26: Direct measurement of the Higgs width becomes possible above $\sim 200$ GeV in the $H \rightarrow 2e2\mu$ channel.
In addition to being a dominant discovery mode, the $H \to ZZ \to 4\ell$ decay mode is a powerful probe of the spin, parity and $CP$. The most general production vertex is given by

$$\frac{igM_Z}{\cos \theta_W} \left( ag_{\mu\nu}^{\mu',\nu',1} + \frac{b}{M_Z^2} p_{1\mu} p_{2\nu} \epsilon^{\mu',\nu',1} + \frac{c}{M_Z^2} \sigma_{\mu\nu\rho\sigma} p_{1\rho} p_{2\sigma} \right)$$

where the first term corresponds to the SM scalar, the second to a non-SM scalar and the third to a non-SM pseudoscalar. $CP$-violation would be present for admixtures of non-zero $a$, $b$ and $c$ in equation (5). The experimental observables are the azimuthal and polar angular distributions. The azimuthal angle $\phi$ is measured between the two planes defined by the leptonic decays of the two $Z$ bosons in the Higgs rest frame, as shown in Figure 27. This yields a distribution

$$F(\phi) = 1 + \alpha \cos \phi + \beta \cos 2\phi .$$

The polar angle distribution has the form

$$G(\theta) = T(1 + \cos^2 \theta) + L \sin^2 \theta .$$

One defines the asymmetry $R = \frac{L - T}{L + T}$ to better distinguish the models. The helicity amplitude of the $|ZZ\rangle$ state to be in the $|00\rangle$ state is predicted to be

$$T_{00} = \frac{M_H^2 - 2M_Z^2}{2M_Z^2} \quad \text{for} \quad M_H > 2M_Z .$$

The value of $R$ for a $S^{CP} = 0^+$ state is $R = \frac{T_{00} - 1}{T_{00} + 1}$ and for a $S^{CP} = 0^-$ state, $R = -1$. The predicted values of $R$ for SM Higgs production are given in Figure 28.
2.1 High Mass Resolution Search Channels

Figure 28: Standard Model prediction for $R$. 
The $H \rightarrow \gamma\gamma$ decay is naturally expected to rise and then drop off on approaching the WW-threshold. This can be seen from the loop-diagrams of Figure 29 which have $Q^2 \approx 4M_H^2$. The negative interference between the top (fermion) and W boson loops decreases the partial decay width by $\sim 10\%$.

The contributions to the total Higgs production cross section at $m_H = 120$ GeV are given in Table 2. The irreducible backgrounds, i.e. those with two real photons in the final state, come from:

- $gg \rightarrow 2\gamma$ (Box diagram)
- $q\bar{q} \rightarrow 2\gamma$ (Born diagram)
- $pp \rightarrow 2\gamma + jets$ with two prompt photons

while the reducible backgrounds come from neutral jets (or hard $\pi^0$’s) that fake one or two photons in the processes $pp \rightarrow \gamma + jet$ and $pp \rightarrow jets$, respectively. The process of two neutral jets faking a pair of high energy photons cannot be reliably simulated with Monte Carlo techniques. Data-driven techniques will be needed to estimate these backgrounds through the process of tightening photon isolation variables using sideband regions of the reconstructed Higgs mass, as in Figure 30.
Figure 30: Reconstruction mass distribution for $H \rightarrow \gamma\gamma$ scale up by $\times 20$ on top of simulated background predictions. The statistics on the background predictions are low.
2.1 High Mass Resolution Search Channels

The overall selection efficiency for Higgs decays to photons at $m_H = 120$ GeV is $\sim 32\%$ with contributions listed in Table 3. The corresponding backgrounds for this selection are given in Table 4 with large uncertainties in the $pp \rightarrow jets$ contribution. For 1 fb$^{-1}$ of integrated luminosity and a 2.5 GeV mass window, the expected number of $H \rightarrow \gamma\gamma$ events is 22 for a background of 535 events, giving an $S/B \sim 4\%$.

Table 4: Estimated background expectations per unit of mass window (fb/GeV) for the $H \rightarrow \gamma\gamma$ inclusive search. A typical mass window is 2.5 GeV.

The predicted $H \rightarrow \gamma\gamma$ search sensitivity depends strongly on the calorimeter resolution, as shown in Figures 31 and 32. Part of the resolution contribution is from primary vertex assignment which correctly assigns the signal vertex in $\sim 83\%$ of the events. The current technique consists of assigning the vertex with the highest $p_T$ track in the event as the $H \rightarrow \gamma\gamma$ signal vertex.

Figure 31: Comparison of signal and background distributions in $H \rightarrow 2\gamma$ for a calorimeter mass resolution of $\sigma_{m_H} = 700$ MeV at $m_H = 120$ GeV.

Figure 32: Comparison of signal and background distributions in $H \rightarrow 2\gamma$ for a calorimeter mass resolution of $\sigma_{m_H} = 900$ MeV at $m_H = 120$ GeV.
The gluon-gluon fusion loop-diagram for Higgs production is necessarily a high $Q^2$ process due to the top quark mass. It was proposed in Reference [S.Abdullin et al., PLB 431: 410-419, 1998] that the search for $pp \rightarrow H \rightarrow \gamma\gamma + jet$ should have a higher signal-to-background ratio than the inclusive search, as shown in Figure 33. The backgrounds are suppressed with a cut on $\sqrt{s} > 300$ GeV, as in Figure 34. This channel also benefits from a more efficient primary vertex-jet assignment, using the tracks of the high $p_T$ jet to assign the signal vertex.

Figure 33: Two leading diagrams for $H \rightarrow 2\gamma + jet$ production. The diagram on the right is $qqH$ weak boson fusion production of the Higgs boson.
Figure 34: Distribution of the differential cross section in $\sqrt{s}$ for the $H \rightarrow 2\gamma + jet$ signal(S) and background(B) processes.
The reduced background-level in \( H \rightarrow 2\gamma + jet \) and in the weak boson fusion Higgs production will provide a flatter background shape on which to measure the mass of a light Higgs boson, as shown in Figures 35 and 36.

Table 5 lists the predicted inclusive \( H \rightarrow 2\gamma \) and exclusive \( H \rightarrow 2\gamma + jet \) cross sections and background levels after event selection from an ATLAS analysis.

2.2 JetMET-Oriented Low-Mass Channels

There are three exclusive channels in the low mass Higgs search which compete with the $H \rightarrow \gamma\gamma$ sensitivity at $m_H = 120$ GeV. These are $t\bar{t}H (H \rightarrow b\bar{b})$, $qqH (H \rightarrow \tau\tau)$ and $qqH (H \rightarrow WW^* \rightarrow 2\ell 2\nu)$, as shown in Figure 37. All of these channels involve jets and transverse missing energy in the final state, and are therefore “JetMET”-related analyses. The resolution of jet $p_T$ measurements are roughly an order of magnitude lower (worse) than corresponding electron, muon or photon measurements, as shown in Figure 40. The lower measurement resolution reduces the reconstruction efficiency of low $p_T$ jets and introduces fake jets formed from low energy background sources.

![Figure 37: ATLAS Higgs search sensitivity in the low mass channels.](image-url)
The cross section for $t\bar{t}$ production at the LHC is $\sim 833$ pb (or a factor $\times100$ larger than at the Tevatron) and therefore an abundant source of events. Figure 38 shows a mock commissioning plot from 150 pb$^{-1}$ of simulated initial data. The cross section for associated Higgs production $t\bar{t}H$ is $\sim 0.7$ pb, three orders of magnitude smaller. The $t\bar{t}H$ search channel suffers from several sources of efficiency loss from branching fractions for $t\bar{t} \to \ell + jets$ and $H \to b\bar{b}$ (total branching fraction $\sim 20\%$), single-lepton trigger inefficiency, event selection when requiring exactly six jets, jet reconstruction, combinatorics of $b$-jet assignment, dijet $b\bar{b}$ mass resolution and $b$-tagging efficiency to the fourth power, $\epsilon_b^4 \approx 11\%$. Figure 39 shows the reconstruction turn-on efficiency for jet reconstruction at an instantaneous luminosity of $\mathcal{L} = 2 \times 10^{33}$ cm$^{-2}$s$^{-1}$ in the CMS calorimeter. At parton-level, the efficiency for the $t\bar{t}H$ channel decreases from $89\%$, $60\%$, $30\%$ to $11\%$ for corresponding $p_T$ cuts on all partons of 10, 20, 30 and 40 GeV. Therefore, the use of tracking and other techniques to sharpen the jet reconstruction efficiencies are essential to maintain low thresholds.

Figure 38: The three-jet hadronic top mass expected from calorimeter commissioning with 150 pb$^{-1}$ of data.
2.2 JetMET-Oriented Low-Mass Channels

Figure 39: Turn-on curve of jet reconstruction efficiency for calorimeter jets in CMS.

Figure 40: Calorimeter jet resolutions.
An example distribution of the reconstructed Higgs mass in the $H \rightarrow b\bar{b}$ decay mode in $t\bar{t}H$ events is shown in Figure 41. The background shoulder is partially due to the $t\bar{t}Z$ background with $Z \rightarrow b\bar{b}$. The $b\bar{b}$ dijet mass resolution is expect to be $\sim 12 - 15\%$ and therefore separating $m_Z$ and $m_H$ will be limited by detector resolutions and calibrations. There is a broad contribution to the mass distribution from $t\bar{t}b\bar{b}$ production from QCD interactions, having more theoretical uncertainties in the shape and cross section than the $t\bar{t}Z$ process.

Another JetMET-related channel is the weak boson fusion production $qqH$ of the Higgs boson with the $H \rightarrow \tau\tau$ decay. In the decay of the Higgs to $\tau$-leptons, a mass reconstruction technique involving the transverse missing energy aides in the separation of the large background from $Z \rightarrow \tau\tau + jets$. Only $\sim 80\%$ of the tau energy is visible in the calorimeter, the remainder is lost to neutrinos. Figure 42 shows how the transverse missing energy can be projected onto the $\tau$-lepton momentum directions to recover part of the undetected tau energy. An example $H \rightarrow \tau\tau$ mass resolution for $m_H = 120$ GeV is shown in Figure 43.

The effectiveness of using the measured $E_T^{\tau}$ depends on the $E_T^{miss}$ resolution and resolution tails. Generally, the
technique in Figure 42 requires a large Higgs $p_T$ in order to avoid false solutions. An example of $E_T$ resolution tails is given in Figure 44 for QCD dijet events, and a similar plot for the resolution as a function of the scalar $\sum E_T$ in Figure 45. The cumulative QCD $E_T$ tails set the lowest thresholds that can be used in the trigger, which is $\approx 1$ Hz for a 100 GeV threshold. For events with no intrinsic $E_T$, the direction of the measured $E_T$ is correlated to the jet and lepton directions, as the mismeasurement of energetic objects is a leading source of $p_T$ imbalance. The construction of an $E_T$ significance, or a simple requirement on the minimum angular separation of the missing energy direction and the nearest jet or lepton, can substantially reduce backgrounds from intrinsically low $E_T$ processes.

Figure 44: Transverse missing energy resolution tails in dijet events.

![Figure 45](image5.png)

Figure 45: Transverse missing energy resolution in dijet events as a function of the scalar $\sum E_T$. 
The selection efficiency for a pair of $\tau$-leptons, such as from $H \to \tau\tau$ decay, has a substantial contribution from hadronic $\tau$ decays, as shown in Table 6. The identification of hadronic tau decays relies on the narrowness and isolation of the tau jet. Figures 46 and 47 show the definition and performance, respectively, of a “shrinking cone” method for separating tau jets from QCD jets. Due to the finite mass of the tau, a higher $p_T$ boost will result in a narrower jet of particles from its decay. The dominant 1-prong and 3-prong decays of the tau and the expected visible mass distribution can be seen selected tau candidates, as shown in Figures 48 and 49 with Tevatron data.

The triggering of $qqH$ with $H \rightarrow \tau\tau$ relies on good hardware tau isolation techniques. Nominally, the signal signature is a four-jet final state with low $E_T$ and therefore has a potentially overwhelming multijet QCD background. However, the kinematics of the forward-jets and the narrowness of the tau jets suppresses the multijet background. The pseudo-rapidity distributions of the jets and taus are plotted in Figure 50.

An important background for the $qqH$ search in the decay $H \rightarrow \tau\tau$ are $t\bar{t}$ events in the dilepton decay mode. The jets coming from this process are more central than forward-tagging jets from weak boson fusion and can be $b$-tagged if they are within the tracker acceptance, or $|\eta| < 2.4$ for CMS. Forward-tagging jets are light quark jets as they originate from valence quark scattering, see Figure 33. Therefore, the use of a central jet veto can be very powerful in reducing $t\bar{t}$ backgrounds. However, with $\sim 5$ multiple interactions at an instantaneous luminosity of $\mathcal{L} = 2 \times 10^{33} \text{cm}^{-2}\text{s}^{-1}$ (including single and doubly diffractive events), there are a number of minbias jets in every event with a $p_T$ spectrum extending above 30 GeV. To maintain an effective central jet veto, the jets must be assigned to a vertex using the tracking information. The tracks of the central $\tau$-jets define the primary vertex, and therefore the jets from the non-signal vertices are ignored in the central jet veto. Jet-vertex assignment will be important for all LHC measurements to reduce the effects of pile-up.

Figure 50: Forward-jet and $\tau$-lepton pseudo-rapidity distributions in the $qqH$ process with $H \rightarrow \tau\tau$. 
2.3 Inclusive Dilepton Analysis

The $H \rightarrow WW$ decay mode has a branching fraction of $\sim 8\%$ at $m_H = 115$ GeV that grows steadily to a maximum of $96\%$ right below the ZZ-threshold. The leptons from $H \rightarrow WW$ tend to point in the same direction, as shown in Figure 51. This provides a natural search variable, namely $\Delta \phi_{\ell\ell}$ the azimuthal angle between the leptons. The high opening angle backgrounds come from $Z \rightarrow \tau\tau$ where both $\tau$-leptons decay leptonically, as shown in Figure 52. The backgrounds in the reconstructed dilepton mass $m_{\ell\ell}$, shown in Figure 53 and 54 from the Tevatron, depend on the flavor combination of the leptons, where the $e\mu$ channel has substantially lower backgrounds from Drell-Yan and $Z \rightarrow \ell\ell$.

![Figure 51: Leptons from $H \rightarrow WW$ decay tend to point in same direction.](image-url)
2.3 Inclusive Dilepton Analysis

Figure 52: The azimuthal opening angle between leptons in the $H \rightarrow WW$ channel from the Tevatron.

Figure 53: Reconstructed dilepton mass in $H \rightarrow WW \rightarrow ee$ channel.

Figure 54: Reconstructed dilepton mass in $H \rightarrow WW \rightarrow e\mu$ channel.
2.3 Inclusive Dilepton Analysis

The $t\bar{t}$, WW and $Z \rightarrow \tau\tau$ backgrounds to the $H \rightarrow WW$ search have differing dilepton kinematics, jet multiplicities and missing energy distributions. As it will be particularly difficult to fully separate samples with differing jet multiplicities and missing energy distributions, it is likely that a simultaneous “inclusive” dilepton analysis will be applied. An example analysis from the Tevatron is shown in Figure 56. In addition, the LHC will have new backgrounds such as flavor excitation production of $gb \rightarrow tW$, as shown in Figure 55.

Figure 55: Flavor excitation processes contributing to the dilepton event selection.

Figure 56: The 2D distributions of jet multiplicities and transverse missing energy for $t\bar{t}$, WW and $Z \rightarrow \tau\tau$ in addition to instrumental and other backgrounds.
Without direct mass reconstruction, as here only the transverse mass is available, a successful search in this channel requires an accurate normalization of standard model contributions to the dilepton event selection and well-described signal kinematics. The transverse mass distribution for $H \to WW$ at $m_H = 160$ GeV is shown in Figure 57. The effect from higher-order corrections on signal kinematics, the Higgs $p_T$ distribution, is shown in Figure 58 and is a source of uncertainty on the dilepton distributions.

![Figure 57: Transverse mass distribution in the $H \to WW \to e\mu\nu\nu$ channel with forward-tagging jet requirements.](image1)

![Figure 58: Leading-order event simulations are reweighted for higher-order corrections to the event kinematics.](image2)
In the sub-threshold region of the $H \to WW$ decay, the requirement of forward-jet tagging, according to the kinematics of $qqH$ production, results in a factor of 10 reduction in background, thereby opening up the low mass search in this channel. Similarly, if the second lepton $p_T$ is too low, then the forward-jets must be included in the trigger decision in order to reduce events from $W + jets$ and multijet QCD background as these would dominate in a single lepton trigger. Forward jets have a transverse momentum of roughly half the W mass, as expected from massive W propagators in the fusion process. The measurement of $qqZ$ production will be an important benchmark for understanding forward jets at the LHC. The tagging jets occur in the pseudo-rapidities $1.5 < |\eta| < 4.5$ as shown in Figure 50 with corresponding energies of $\sim 300$ GeV or higher. Figure 59 shows an $\eta$-$\phi$ map of a $qqH$ event with identified forward jets. There is a slow narrowing of jets with energy, according to the $Q^2$ of the jet production, that goes approximately as $E^{-1/4}$. Therefore tagging jets have a narrower energetic core than backgrounds consisting of boosted low energy jets, minbias pile-up and remnants from the underlying event.

![Higgs decay products and forward jets map](image)

Figure 59: An $\eta$-$\phi$ map of a $qqH$ event with identified forward jets.
As shown in Figure 37, the $qqH$ channel with $H \rightarrow WW^*$ loses sensitivity when the effective $W^*$ mass goes below $\sim M_W/2$. To continue the $H \rightarrow WW^*$ search down to lower masses, the $WH$ production channel can be used. In this channel, there are two nearly on-shell W bosons in the $WH \rightarrow WWW^*$ process. The hard dilepton $p_T$ spectra in this channel increase trigger efficiencies and open up the possibility of a same-sign dilepton search for half of the sample. This signature has very low physics backgrounds especially for dissimilar lepton flavors in the $e^\pm \mu^\pm$ channel. The soft third lepton may be above reconstruction thresholds, especially for muons, and therefore introduce the trilepton signature. The trilepton and same-sign dilepton searches are high purity analyses and have mainly diboson and instrumental backgrounds. The rejection of the $Z$ peak in the $WWW^*$ signature is effective in removing diboson backgrounds, as shown in Figure 60. The $ZH$ production mechanism would be another source of enhanced triple boson production. The performance of the $WWW^*$ same-sign dilepton search has been studied at the Tevatron for the low mass Higgs search and has the most stringent cross section exclusion, as plotted in Figure 61.

![Figure 60](image)

Figure 60: Presence of a $Z$ peak in dilepton combinations from $ZZ$ and $WZ$ backgrounds are rejected in the trilepton $WH \rightarrow WWW^*$ channel. The $ZZ$ backgrounds with $Z \rightarrow \tau\tau$ fall into the signal region as indicated by the boxed region.
Figure 61: Overall summary of Standard Model Tevatron Higgs searches showing the $WVV^*$ exclusion limits.
2.4 Boosted Dibosons from Heavy Higgs Decay

As shown in Figure 26, the natural width of the Higgs boson exceeds 100 GeV for a mass of $m_H = 600$ GeV and above, and the total production rate drops to below 1 pb with a significant fraction of the total rate coming from $qqH$ production. To cover this heavy mass region, additional decay channels of $H \to WW$ and $ZZ$ need to be utilized. The highly boosted W and Z bosons coming from an 800 GeV Higgs boson decay will have collimated decay products, as drawn in Figure 62 for the strong WW scattering process. The hadronic decays appear as single jets in the detector. The mass of the single jet can be used to identify the jet as originating from a W or Z boson, as shown in Figure 63. The $qqH$ production mode with $H \to WW \to \ell vjj$ and $H \to ZZ \to \ell \ell jj$ decay modes benefit from the higher branching ratios of the hadronic boson decay, and the identification of a massive single jet is an effective part of the event signature. A similar high branching ratio decay channel is the $H \to ZZ \to \ell \ell \nu \nu$ in $qqH$ production. This provides a large transverse missing energy signature as shown in Figure 64.

2.5 From 115 GeV to 1 TeV

An overview of the Standard Model Higgs search sensitivity with the CMS experiment is shown in Figure 65.

![Figure 65: Estimates of the statistical significance of the Standard Model Higgs boson searches with 30 fb$^{-1}$ of integrated luminosity.](image)

The LHC Higgs search has a broader variety of possible analyses than those developed at LEP. Furthermore, the experimental challenges are starkly different in the different search topologies and mass ranges. The high mass resolution channels depend strongly on the calibration and alignment of the tracking, calorimeters and muon spectrometers and are subject to intense commissioning efforts. The JetMET-related search channels must contend with the low $p_T$ jet reconstruction efficiencies and fake rates. The usage of the transverse missing energy in these channels is also subject to commissioning and the effects of detector noise, jet mismeasurement response tails and minbias pile-up. For weak boson fusion search topologies, the forward-tagging jets will be nearly the highest pseudo-rapidity jets used for analysis in hadronic collisions, creating an uncertainty in the reliability of simulations of the jet backgrounds in the forward regions. In cases where the search channel depends on efficient $\tau$-lepton triggering or on single lepton triggers plus jets, techniques for data-driven background calculations must be applied to correctly account for multijet QCD backgrounds and instrumental backgrounds enhanced by the trigger selection. Inclusive analyses, such as the dilepton analysis, will have to address a wide variety of standard model processes, some never measured before. The same-sign dilepton and trilepton searches will address rare backgrounds processes with unknown contributions from fake and misreconstructed leptons,
requiring data-derived estimates. Heavy Higgs searches will require dedicated treatment of highly boosted W and Z boson decays.

In general, the understanding of the searches starts at high $p_T$ and moves towards lower masses. It would not be surprising in the LHC Standard Model Higgs search to see a rapid exclusion for Higgs boson masses above $m_H \approx 150$ GeV and extending up to 500 GeV, and then followed by more detailed experimental efforts as discussed here to cover the low mass region down to $m_H = 115$ GeV and the high mass region up to 1 TeV.
